Abstract: Background: Previous studies have shown oxidative stress in pemphigus vulgaris and pemphigus foliaceus, nevertheless, it remains unknown whether a similar response is characteristic of endemic pemphigus foliaceus in Peru.

Objectives: To determine the oxidative stress response in endemic pemphigus foliaceus patients and subjects with positive for anti-desmoglein 1 antibodies (anti-dsg1) from endemic areas of Peru.

Subjects and methods: This is a cross-sectional study. The study population included 21 patients with Endemic Pemphigus foliaceus and 12 healthy subjects with anti-dsg1 antibodies from the Peruvian Amazon (Ucayali), as well as 30 healthy control subjects. Malondialdehyde, an indicator of lipid peroxidation by free radicals, was measured in serum.

Results: We collected 21 cases of endemic pemphigus foliaceus, 15 of them with active chronic disease and 6 in clinical remission. Serum malondialdehyde values in patients with chronic active evolution and healthy subjects with anti-dsg1 antibodies were statistically higher than those of healthy controls (p<0.001). There was no significant difference between serum values of localized and generalized clinical forms.

Study limitations: The main limitation of this present study is the small number of patients with endemic pemphigus and healthy subjects positive for desmoglein 1 antibodies.

Conclusions: The increased serum levels of malondialdehyde in patients with chronic active endemic pemphigus foliaceus and healthy subjects from endemic areas with anti-dsg1 antibodies may suggest a contribution of systemic lipid peroxidation in the pathogenesis of endemic pemphigus foliaceus.

Keywords: Malondialdehyde; Oxidative stress; Pemphigus; Peru

INTRODUCTION

Endemic Pemphigus foliaceus (EPF) or Fogo Selvagem is an autoimmune skin disease characterized by the appearance of superficial subcorneal blisters and anti-epidermic circulating autoantibodies, predominantly IgG4, directed against the desmosomal glycoprotein of the cadherin group known as Desmoglein 1 (dsg1).1 EPF can be seen in rural areas of some states of Brazil, Colombia, Paraguay, Peru and Tunisia.2-6

In Peru, EPF foci have been described mainly within the department of Ucayali.7,8 A previous study from our group indicated that 8% of the patients with endemic skin diseases from 3 locations within the Amazon rainforest were diagnosed with EPF.8

It has been suggested that healthy subjects exposed to the local ecology of the endemic focus produce anti-dsg1 antibodies due to exposure to environmental factors.7 The exposure to hema-
tophagous insects would trigger an immune response in patients with EPF. There is a high prevalence of black flies (87%), kissing bugs (67%), and bed bugs (60%) bites in EPF patients. Moreover, some endemic areas for EPF coincide with endemic areas of cutaneous leishmaniasis and Chagas disease. Our group found that of 41 healthy subjects from the endemic focus of Pueblo Libre (Ucayali, Peru), 31.7% were positive for anti-dsg1 antibodies.

Previous studies indicated that the oxidative stress response is increased in patients with pemphigus vulgaris (PV) and PF. Furthermore, a positive correlation between anti-dsg1 levels and oxidative markers levels has been recently described. These observations suggest that healthy subjects with anti-dsg1 may also have an increase in their serum oxidative markers.

Damage by reactive oxygen species is a consequence of an oxidative/antioxidative imbalance. This damage is mediated by reactive oxygen species that react with lipids, proteins and nucleotides. Lipid peroxidation occurs when peroxidant components react with unsaturated fatty acids of lipid membranes and produce changes in its physical and chemical properties, thus, altering cell permeability to fluids and increasing the risk of cell membrane rupture.

To our knowledge, no studies have been carried out in Latin American subjects with EPF. Therefore, our objective is to investigate whether alterations in the oxidative stress response occur in patients with EPF and in healthy subjects with positive anti-dsg1 antibodies from endemic areas of Peru.

METHODS

This is a cross-sectional study including patients from Lima and Ucayali, carried out between January 2006 and December 2007. Lima is a non-endemic area for PF, while some geographic areas of Ucayali (Campo Verde, Calleria and Nueva Requena) are endemic focus for PF and is located in the Amazon rainforest. The study population included 21 patients with EPF and 12 healthy subjects with anti-dsg1 antibodies from Ucayali, as well as 30 healthy control subjects from Lima.

Subjects were included if they were 18 years or older and capable of giving informed consent. Subjects with chronic concomitant medical conditions, as well as subjects with acute diseases were excluded. Subjects were divided in four groups, (1) subjects with chronic active evolution, (2) subjects with disease remission, (3) healthy subjects positive for anti-dsg1 antibodies and (4) healthy control subjects. Samples from patients with active disease were obtained just before starting treatment. Patients in remission were undergoing treatment receiving systemic corticosteroids.

All participants were subjected to a full body skin examination. Blood samples and skin biopsies were collected to determine the presence of anti-dsg1 antibodies (analyzed by ELISA, indirect and direct immunofluorescence), as previously described. All sera were separated and stored at -80°C until used.

We quantified malondialdehyde (MDA) as thiobarbituric acid reactive substance (TBARS), following the method of Buege and Aust with some modifications, which is based in the reaction of MDA with thiobarbituric acid (TBA). In the TBA test reaction, MDA and TBA react to form a pink pigment. Procedure used 0.5ml plasma, with 1 ml of trichloroacetic acid (TCA 20%) was added and the tube was left to stand for 10 min at room temperature. After centrifugation at 3,500rpm for 10 min, the supernatant was separated. Thereafter, 0.5ml of the supernatant was added to 0.5ml of thiobarbituric acid (TBA) and incubated in a boiling water bath for 30 min. After cooling in cold water, the absorbance was read at 532nm. TBARS concentration was calculated using $1.56 \times 10^{-5} \text{M} \cdot \text{cm}^{-1}$ as mol/L extinction coefficient. The results were expressed as $\mu$mol/L. The MDA levels of oxidative stress and desmoglein 1 antibodies were obtained from plasma and serum respectively.

For the statistical analysis SPSS version 22.0 (SPSS Inc., Chicago, IL, USA) was used. Univariate analysis was performed with frequencies, percentages, media, medians and standard deviation. Plots were used to describe the MDA levels and their median.

The study was approved by the board members of research and ethics of the Clinical Research Institute at Universidad Nacional Mayor de San Marcos, Lima, Peru.

RESULTS

Twenty-one patients with EPF, 12 healthy subjects from endemic areas, and 30 healthy controls from non-endemic areas were enrolled in this study. Fifteen patients presented with active chronic disease and 6 patients were in clinical remission. Patients had subcorneal acantholysis in their histopathological examinations and were positive for anti-dsg1 antibodies in immunological probes (ELISA 63.6%, direct immunofluorescence 9.1% and indirect immunofluorescence 37.3%). Demographic characteristics for each group are summarized in table 1. The disease was more frequent in females, children and young adults.

Levels of lipid peroxidation were compared between groups by measuring MDA serum concentrations, as indicated in the methods section. In patients with the localized clinic form, serum MDA values were between 2.4 and 11.4µmol/L, for the generalized clinical form were between 2.9 and 11.4µmol/L (p = 0.591) (Graph 1).

In patients with chronic active disease, MDA values were between 2.35 and 11.4µmol/L; these levels were higher than controls (Table 1). Patients in clinical remission had serum levels of MDA between 0.40 and 4.18µmol/L (Graph 2, Table 1). Healthy subjects from endemic areas who tested positive for antibodies anti-dsg1 also had serum levels of MDA higher than the controls, ranging between 0.38 and 8.36µmol/L; while that in the control group serum MDA levels were between 1.49 and 2.59µmol/L. There was statistically significant difference between the groups based on the MDA levels (Kruskal Wallis; p<0.001). The results of the Dunn-Bonferroni test are showed in table 2.

There was no correlation between the serum concentration of MDA and age ($r = 0.105; p=0.721$). Moreover, there was no statistically significant difference in the serum concentration of MDA between males and female patients (U-Mann Whitney Test; p=0.196).

DISCUSSION

Recent studies have demonstrated the existence of higher levels of lipid peroxidation in several skin diseases such as vitiligo, rosacea and acne; in skin conditions with systemic component such as psoriasis and pemphigus vulgaris, as well as in systemic diseases with cutaneous manifestations, i.e., systemic lupus erythematosus, Behcet’s disease and systemic sclerosis.10,11,16-24 These studies propose that an imbalance of the oxidative/antioxidant response is necessary for disease pathogenesis or activation.

Only a few studies evaluating the oxidative state in blistering diseases have been done, including patients with pemphigus vulgaris and/or pemphigus foliaceus.10-13 Naziroglu et al.13 found higher MDA levels in the serum of patients with PV in comparison to healthy controls. Abida et al.15 obtained similar results between the sera from patients with PV and PF, which were higher than healthy controls. In another study, Abida et al.16 demonstrated that MDA concentrations were higher in biopsies of lesions from patients with PF and in biopsies from non-lesional skin from PF patients than in biopsies from healthy control subjects. However, no studies have investigated the endemic forms of these two diseases. To our knowledge our study is the first one that illustrates the presence of abnormalities in the oxidative response from patients with EPF in South America.

Altogether, our results and those from other studies, i.e., (1) the positive correlation between anti-dsg1 levels and MDA levels, 2) the observation of increased MDA levels in biopsies from non-lesional skin from PF patients, and 3) the increased MDA levels in healthy subjects with positive anti-dsg1 antibodies suggest that the increase in the oxidative response might precede or concur with the development of skin lesions and it may play a role in the pathogen-

Oxidative stress in patients with endemic pemphigus foliaceus and healthy subjects with anti-desmoglein 1 antibodies

RESUSCITATION. The disease, Abida et al. (14) proposed that the increase of reactive oxygen species and lipid peroxidation might induce oxidative changes in the structure of Dsg1 and Dsg 3 and therefore would make them potential targets for autoantibodies inducing acantholysis. However, further studies are needed to determine whether the alteration in the oxidative response precedes or not the development of anti-dsg1 antibodies.

Our results also indicate that patients in clinical remission have higher values of serum MDA, which is greater than the controls and less than those of patients with chronic active form. These results suggest that even though there is remission from the clinical and immunological standpoint (less values and titles in ELISA and IFI); there is still biochemical activity of the disease. As a result, determination of MDA in serum could constitute an indicator of disease activity in the group of EPF patients without comorbidities. It is noteworthy to mention, that the localized and generalized clinical forms show similar MDA levels, which suggests that the extension of the disease has no implications in the levels of lipid peroxidation.

Based on our results and previous studies, future research exploring the use of antioxidants (external supplementation or in regular diet) in reducing the oxidative stress is guaranteed.\(^{12,13}\)

Moreover, it would be necessary to establish if antioxidants could be used not only as adjuvant therapy on patients with endemic pemphigus but also as prophylaxis in healthy subjects positive for desmoglein 1 antibodies.

The main limitation of this present study is the small number of patients with endemic pemphigus and healthy subjects positive for desmoglein 1 antibodies; however, the results are still relevant in the studied subjects.

CONCLUSIONS

In conclusion, this study indicates that patients with chronic active EPF and healthy subjects of endemic areas with anti-dsg1 antibodies have systemic oxidative alterations. This may suggest a contribution of systemic lipid peroxidation in the pathogenesis of EPF; however, it is still necessary further research to confirm whether oxidative stress occurs as direct consequence of the inflammatory response in this disease.
