Self-potential, soil CO₂ flux, and temperature on Masaya volcano, Nicaragua

J. L. Lewicki,^{1,2} C. Connor,¹ K. St-Amand,³ J. Stix,⁴ and W. Spinner¹

Received 13 May 2003; revised 1 July 2003; accepted 9 July 2003; published 13 August 2003.

[1] We investigate the spatial relationship between self-potential (SP), soil CO₂ flux, and temperature and the mechanisms that produce SP anomalies on the flanks of Masaya volcano, Nicaragua. We measured SP, soil CO₂ fluxes (<1 to 5.0×10^4 g m⁻² d⁻¹), and temperatures (26 to 80°C) within an area surrounding a normal fault, adjacent to Comalito cinder cone (2002–2003). These variables are well spatially correlated. Wavelengths of SP anomalies are ≤ 100 m, and high horizontal SP gradients flank the region of elevated flux and temperature. Carbon isotopic compositions of soil CO₂ ($\delta^{13}\text{C} = -3.3$ to -1.1%) indicate a deep gas origin. Given the presence of a deep water table (100 to 150 m), high gas flow rates, and subsurface temperatures above liquid boiling points, we suggest that rapid fluid disruption is primarily responsible for positive SP anomalies here. Concurrent measurement of SP, soil CO₂ flux, and temperature may be a useful tool to monitor intrusive activity.

1. Introduction

[2] Self-potential (SP) anomalies have been observed within many volcanic and hydrothermal regions, and SP variations have been linked to changes in volcanic activity and hydrothermal fluid flow [e.g., Corwin and Hoover, 1979; Fitterman and Corwin, 1982; Massenet and Pham, 1985; Zlotnicki and LeMouel, 1988; Hashimoto and Tanaka, 1995; Zlotnicki et al., 2003]. Monitoring these anomalies on active volcanoes may therefore be a valuable tool to forecast eruptions and understand interaction between magmatic and groundwater systems. SP anomalies have commonly been attributed to electrokinetic (EK) processes involving transport of charge contained in the electrical diffuse layer at the pore surface by electrolyte

solution flow [e.g., Anderson and Johnson, 1976; Massenet and Pham, 1985; Revil et al., 1999; Ishido and Pritchett, 1999]. However, Johnston et al. [2001] proposed that rapid fluid disruption (RFD), a process whereby charge separation can be produced by rapid disruption or vaporization of liquid water by high heat and/or gas flow, may be primarily responsible for SP anomalies observed in many volcanic areas. Unlike EK potentials, which are commonly produced by capillary flow of aqueous solutions, RFD may produce SP anomalies in thermal areas far above the groundwater table as charge is carried by water droplet and/or vapor flow [Johnston et al., 2001].

[3] The integration of soil gas flux and chemistry, temperature, SP, and hydrologic data should elucidate the mechanism(s) that produce SP anomalies on active volcanoes and therefore improve the use of SP in volcano monitoring. We present soil CO₂ flux, temperature, and SP data measured concurrently on the flanks of Masaya volcano, Nicaragua (Figure 1) and show that these data are well spatially correlated. We suggest that RFD may be the primary mechanism to produce SP anomalies at Masaya and that tracking the relative temporal changes in SP and soil CO₂ flux may serve as an important volcano monitoring tool.

2. Methods

[4] The study area, located adjacent to Comalito cinder cone (Figure 1) is characterized by fumarolic steam emissions along an inferred normal fault. Evidence of high gas and heat flow [St-Amand, 1998; Pérez et al., 2000] and basic understanding of the shallow groundwater system [Sandberg and Connor, 2002] make this an excellent location to investigate correlation of gas flux and SP. In August, 2002, 209 measurements of soil CO₂ flux and temperature were made at uneven spacing within a 7175 m² area adjacent to Comalito (Figures 1 and 2). In February–March, 2003, 469 measurements of CO₂ flux, temperature, and SP were made at one-m spacing along four traverses that crossed perpendicular to an inferred normal fault located within the same study area. Twenty-three soil gas samples were collected at 75 cm depth from within or near this area in March, 1997 and February, 1998.

[5] CO₂ flux was measured using the accumulation chamber (AC) method [e.g., Chiodini et al., 1996] with a LI-COR LI-800 infrared gas analyzer. Measurement accuracy and repeatability of the AC method are -12.5% [Evans et al., 2001] and $\pm 10\%$ [Chiodini et al., 1998], respectively. Soil temperature was measured at 20 cm depth by thermocouple. SP was measured using two Cu/CuSO₄ non-polarizing electrodes, an insulated Cu cable, and a digital multimeter. SP measurements along each traverse are

referenced to the first station at the southwest end of each traverse. Carbon isotope ratios of soil CO₂ were measured by dual-inlet gas-isotope mass spectrometry (measurement error = $\pm 0.4\%$). Carbon-13 data are reported as $\delta^{13}\text{C}$, the deviation, in parts per thousand (‰) of the $^{13}\text{C}/^{12}\text{C}$ ratio in the sample from that of the Pee Dee belemnite (PDB) reference standard.

3. Results

[6] CO₂ fluxes and temperatures measured in 2002 ranged from 27 to $4.2 \times 10^4 \text{ g m}^{-2} \text{ d}^{-1}$ (Figure 2) and 30 to 80°C, respectively. Fluxes are log-normally distributed into two overlapping populations [Sinclair, 1974]. Log fluxes and soil temperatures are well positively correlated (correlation coefficient, $C = 0.81$). An interpolated (Kriging method) image map (Figure 2) shows that elevated fluxes are distributed along linear trends sub-parallel to the fault. Multiplying the mean of the Kriged CO₂ flux data ($2750 \text{ g m}^{-2} \text{ d}^{-1}$) by the sampling area (7175 m^2), total CO₂ discharge from this area is $\sim 20 \text{ tons day}^{-1}$. Carbon-13 values of soil CO₂ range from -3.3 to -1.1% .

[7] CO₂ fluxes and temperatures measured in 2003 along transects C1–C4 ranged from <1 to $5.0 \times 10^4 \text{ g m}^{-2} \text{ d}^{-1}$ and 26 to 79°C, respectively (Figure 3). Wavelengths of SP anomalies are $\leq 100 \text{ m}$. High horizontal SP gradients flank the region of elevated flux and temperature (e.g., 26 mV m^{-1} on SW side of transect C1). Log CO₂ flux and soil temperature are well positively correlated ($C = 0.84, 0.86, 0.86$, and 0.92 for transects C1, C2, C3, and C4, respectively). Self-potential is well positively correlated with soil temperature ($C = 0.81, 0.84, 0.79$, and 0.81 for transects C1, C2, C3, and C4, respectively) and moderately correlated with flux ($C = 0.67, 0.71, 0.59$, and 0.70 for transects C1, C2, C3, and C4, respectively).

4. Discussion and Conclusions

[8] Soil CO₂ fluxes measured on the flanks of Masaya are among the highest reported for volcanoes worldwide, in-

cluding Cerro Negro, Nicaragua [Salazar *et al.*, 2001], Solfatara, Italy [Chiodini *et al.*, 2001], and Mammoth Mountain, USA [Farrar *et al.*, 1995]. Observed spatial trends in soil CO₂ fluxes and temperatures and good correlation between these variables are indicative of advective transport of heat and CO₂ with steam along a highly permeable fault zone.

[9] The age of Comalito is unknown; however, we measured elevated soil CO₂ fluxes and temperatures, up to $1.4 \times 10^4 \text{ g m}^{-2} \text{ d}^{-1}$ and 78°C, respectively, on the cone rim in February, 2003. The source of gas and heat at our study site may therefore be a cooling intrusion at relatively shallow depth, related to Comalito. Also, $\delta^{13}\text{C}$ values indicate that soil CO₂ is likely a mixture of CO₂ from mantle (-9 to -4% ; Pineau and Javoy [1983]) and marine carbonate ($0 \pm 4\%$; Ohomoto and Rye [1979]) sources.

[10] Observed correlation of SP with both soil CO₂ flux and temperature suggests that electrical current density is proportional to fluid flow at the ground surface where outflow conditions exist. Higher correlation of SP with soil temperature than CO₂ flux may be attributed to the dominant mechanisms of gas and heat transport. Advective transport of CO₂ through highly permeable fractures is likely the dominant mode of CO₂ flow here [e.g., Xu and Pruess, 2001]; surface CO₂ fluxes will therefore be relatively highly spatially variable. Heat transport is likely a combination of advection through fractures and conduction through the surrounding media. We therefore expect soil

Figure 2. Interpolated (Kriging method) image map of log CO₂ flux measured adjacent to Comalito cinder cone. White dashed line and dots show locations of inferred normal fault and soil CO₂ flux and temperature measurements (temperature data not shown), respectively. Also shown are locations of transects C1–C4.

Figure 3. Plots of log CO₂ flux and soil temperature versus distance along transects (a) C1, (c) C2, (e) C3, and (g) C4 (see Figure 2). Dots and pluses are log CO₂ flux and soil temperature, respectively. Plots of SP versus distance along transects (b) C1, (d) C2, (f) C3, and (h) C4.

temperature to be less spatially variable. Because SP is a potential field measurement, it is less sensitive to small scale heterogeneities in the porous fractured media, and spatial trends should more closely resemble those of temperature.

[11] Transient electromagnetic soundings [Sandberg and Connor, 2002] indicate depth to the water table at the study site is 100 to 150 m and high resistivities (~ 1000 ohm-m) in the geologic section above the groundwater table. This is consistent with shallow (<5 m) terrain conductivity measurements made at the study site in 2003, which yield resistivities of 400 to 1500 ohm-m. To evaluate whether EK effects from near-surface fluid flow can account for observed SP anomalies, we calculated the SP anomaly arising from a uniformly polarized thin vertical sheet in a homogeneous subsurface with a top at 100 m depth (i.e., minimum depth to the water table) [Babu, 2003]. The wavelength of the calculated SP anomaly is $\gg 100$ m and the horizontal gradient of the anomaly is much less than those observed along transects C1–C4 (Figure 3). Polarization must be shallow (<10 m) to produce the high horizontal SP gradients observed at the study site. It is therefore unlikely that observed SP anomalies are due in large part to EK effects, as proposed by Johnston *et al.* [2001] for similar observations near active vents on Kilauea. Given the presence of mechanisms to produce RFD (i.e., subsurface temperatures above liquid boiling points, high

gas flow rates), a thick unsaturated zone, and relatively high resistivities, it is likely that SP anomalies are mainly produced by RFD, although some contribution from EK effects due to shallow two-phase flow [e.g., Antraygues and Aubert, 1993] may also be occurring.

[12] The concurrent temporal measurement of SP, soil temperature, and CO₂ flux may be used to monitor intrusive activity. Injection of magma to relatively shallow crustal levels should be accompanied by increased magmatic heat and gas flow. As the heat and gas interact with the shallow groundwater system, RFD could occur. In this case, we expect that a positive SP anomaly will be formed at the surface in conjunction with elevated CO₂ discharge. Soil temperature anomalies may be slower to follow, due to the combined effects of conductive and advective heat transport. As magma continues to rise to near-surface levels, a groundwater dry-out zone will form around the intrusion above which we predict increased surface temperatures and magmatic gas flow rates to occur in the absence of SP anomalies. Integration of these geochemical and geophysical methods should be further investigated as a volcano monitoring tool.
